

Need of throw keyword:

The keyword throw is used for throwing an exception from a method/constructor when wrong inputs are passed into our method/constructor.

By throwing an exception we are terminating our method/constructor logic execution and informing to method/constructor caller the passed values are wrong.

So that method caller will catch this exception and display the error message to end-user.

Then by reading this error message, end-user will pass correct values to execute program correctly.

Best example: gmail.com [usr and pwd validation](#)
